Supplementation and therapeutic use of vitamin D in patients with multiple sclerosis: Consensus of the Scientific Department of Neuroimmunology of the Brazilian Academy of Neurology

Doralina Guimarães Brum\(^1\), Elizabeth Regina Comini-Frota\(^2\), Cláudia Cristina F. Vasconcelos\(^3\), Elza Dias-Tosta\(^4\)

ABSTRACT
Multiple sclerosis (MS) is an inflammatory, autoimmune, demyelinating, and degenerative central nervous system disease. Even though the etiology of MS has not yet been fully elucidated, there is evidence that genetic and environmental factors interact to cause the disease. Among the main environmental factors studied, those more likely associated with MS include certain viruses, smoking, and hypovitaminosis D. This review aimed to determine whether there is evidence to recommend the use of vitamin D as monotherapy or as adjunct therapy in patients with MS. We searched PUBMED, EMBASE, COCHRANNE, and LILACS databases for studies published until September 9th, 2013, using the keywords “multiple sclerosis”, “vitamin D”, and “clinical trial". There is no scientific evidence up to the production of this consensus for the use of vitamin D as monotherapy for MS in clinical practice.

Keywords: vitamin D, multiple sclerosis, experimental autoimmune encephalitis.

Resumo
A esclerose múltipla (EM) é uma doença inflamatória, autoimune, desmielinizante e degenerativa do sistema nervoso central. Estudos epidemiológicos têm identificado associações de hipovitaminose D com doenças autoimunes. O principal objetivo desta revisão é responder se há evidências que indiquem o uso terapêutico de vitamina D em monoterapia para pacientes com EM. Por meio dos sites PUBMED, EMBASE, LILACS e Scielo foram realizadas buscas usando os descritores “vitamin D”, e “multiple sclerosis” até 12/09/2013. Estudos clínicos randomizados, controlados e duplo-cegos foram selecionados para avaliar a resposta terapêutica da vitamina D na EM. Não foram encontradas evidências científicas que justifiquem o uso da vitamina D em monoterapia no tratamento da EM, na prática clínica.

Palavras-chave: Vitamina D, esclerose múltipla, encefalite autoimune experimental.

Conflict of interest: The Brazilian Academy of Neurology (ABN) is committed to produce clinical guidelines critically and independently. This guideline is part of ABN’s continuing education activity. Its purpose is not to address the subject in its entirety. Treatment decision is shared between patient and physician and according to each situation.

Support: This guideline was developed with financial support from the Brazilian Academy of Neurology. None of the authors received honoraria for their participation.

The conflict of interest form for the issue specifically addressed in this article was signed by all authors.

External collaborators: Alessandro Farias (researcher), Eduardo Antônio Donadi (immunologist), and Marcelo de Paula Corrêa (meteorologist).

Received 10 January 2014; Accepted 20 January 2014.
The therapeutic use of vitamin D for treating multiple sclerosis (MS) is a controversial issue that is of interest to physicians, researchers, and patients. The Scientific Department of Neuroimmunology (DCNI) of the Brazilian Academy of Neurology (ABN) organized a meeting on September 12, 2013, to discuss the basic aspects of vitamin D metabolism, results of in vitro and experimental studies on experimental autoimmune encephalomyelitis (EAE), and controlled clinical trials of vitamin D in MS. Neurologists and researchers participating in the meeting approved a guideline consensus to guide Brazilian neurologists in the care of patients with MS.

**VITAMIN D, MS, AND EAE**

Vitamin D is an important hormone for calcium homeostasis and bone metabolism. Besides its action in bone tissue, vitamin D has a role in cell differentiation, cell growth inhibition, and immune system modulation. The main source of vitamin D is ultraviolet-B radiation (95%). However, no consensus has been reached on optimal serum vitamin D levels for human metabolic needs. The association between vitamin D and autoimmune diseases and neoplasms has been established in recent years, but this relationship has not yet been fully elucidated.

Multiple sclerosis is an inflammatory, autoimmune, demyelinating, and degenerative central nervous system (CNS) disease, whose geographic and ethnic distribution is characterized by a higher prevalence in northern hemisphere countries, particularly in populations of Caucasian origin.

The predominantly temperate climate in the northern hemisphere with long periods of low solar radiation and the relatively high prevalence of hypovitaminosis D observed in population studies have led to the hypothesis that this deficiency may explain the geographical distribution of MS. Moreover, it has been suggested that adequate serum levels of vitamin D could help reduce the risk of developing MS.

Even though the etiology of MS has not yet been fully elucidated, there is evidence that genetic and environmental factors interact to cause the disease. Among the main environmental factors studied, those more likely associated with MS include certain viruses, smoking, and hypovitaminosis D. The latter is particularly important in the northern hemisphere, where the seasonal variation and subsequent reduction in ultraviolet-B radiation in winter may lead to a higher prevalence of hypovitaminosis D. Some conditions represent risk of hypovitaminosis D in the general population such as long stay indoors, use of sunscreen, and skin pigmentation. Motor limitations associated with later stages of MS may contribute to the occurrence of hypovitaminosis D in this group of patients.

Unlike northern hemisphere countries, solar radiation in Brazil is believed to be plentiful in all seasons and regions to prevent hypovitaminosis D. Thus, the amount of sunlight one is exposed in Brazil should be enough to avoid hypovitaminosis D in healthy individuals when exposed to sunlight even for short periods. Nevertheless, no studies have compared serum vitamin D levels among Brazilian regions, whereas few studies have analyzed serum vitamin D levels in a selected risk group.

Preliminary experimental studies have demonstrated an immunomodulatory role of vitamin D on human immune cells in vitro and in an experimental animal model (EAE). An in vitro study with peripheral blood cells of patients on vitamin D therapy showed that serum levels above 40 ng/ml may exert modulatory action on immune cells. Additional studies are underway to better understand this immunomodulatory effect on autoimmune diseases.

**RANDOMIZED AND CONTROLLED CLINICAL TRIALS WITH VITAMIN D IN THE TREATMENT OF MS**

To evaluate the therapeutic response of vitamin D in MS patients, we selected double-blind, randomized, controlled clinical trials from the literature. These studies are still scarce and most were not designed to evaluate therapeutic response to vitamin D. Next, we discuss the most relevant studies.

A clinical study conducted in Finland in 66 patients with relapsing-remitting multiple sclerosis (RRMS) compared a group with 34 patients using 20,000 IU/week of vitamin D and interferon beta-1b (IFNβ-1b) to another group with 32 patients using IFNβ-1b only. In that study, primary outcomes included tolerability and safety aspects, and number of new lesions and gadolinium enhancing lesions on MRI scans. Secondary outcomes included clinical parameters such as annual relapse rate and changes in the Expanded Disability Scale Score (EDSS), in addition to other imaging parameters. The authors observed that the treated group showed fewer new T2 lesions, but there were no significant differences in clinical parameters between the two groups after 12 months. However, there was a significant reduction in the number of gadolinium enhancing lesions in the vitamin D group.

Another study, conducted in Norway, compared bone mineral density, relapse frequency, disease progression, and motor function measures between 35 patients with MS using 20,000 IU of cholecalciferol per week associated with 500
mg/day of calcium and a control group of 33 patients with MS using 500 mg/day of calcium only for two years. Patients in both groups had been previously using immunomodulatory drugs (interferon beta or glatiramer acetate) for a similar period of time. No differences in annual relapse rate and changes in functional capacity measured by EDSS were observed between the two groups, even though vitamin D levels ranged from 24.72 ng/ml in the placebo group to 49.26 ng/ml in the vitamin D group. The study was not powered to address clinical outcomes.

A phase II study developed in Iran compared 25 patients with RRMS receiving the active form of vitamin D (calcitriol) at a dose of 0.25 µg/day with patients receiving placebo. Both groups used conventional immunomodulators. There was no difference in the EDSS between the calcitriol and placebo groups after 12 months followup. It should be noted in that study the small sample size and inclusion criterion of serum 25-hydroxyvitamin D level >40 ng/ml.

A randomized study in Australia compared 11 patients with RRMS treated with vitamin D2 in a dose of 6,000 IU twice daily in addition to a daily low-dose (1,000 IU) with 12 patients receiving the 1,000 IU/day dose only. The neuraxial index of inflammatory activity on MRI was compared between the high-dose and low-dose groups. No significant differences between the groups were detected.

A meta-analysis of the studies cited above detected no difference in the number of relapses between the groups. The number of new lesions and gadolinium enhancing lesions were compared to serum vitamin D levels in other two studies and the findings were conflicting. Limitations of the studies include different dosages and forms of vitamin D administered.

In contrast to epidemiological and experimental studies, randomized trials on the use of vitamin D in MS showed no significant differences in the parameters of disease activity – relapse rate, EDSS progression, and new or gadolinium enhancing lesions on MRI – between the group receiving vitamin D and groups receiving placebo or a smaller dose of vitamin D. These differences and other contradictions indicate the need to conduct double-blind, randomized, controlled trials in large groups of patients, considering the differences between clinical, neuroimaging, biological, and immunological variables, and powered to accurately estimate the therapeutic efficacy and possible side effects of vitamin D in MS.

**VITAMIN D AND OTHER ISSUES**

**Normal range**

The Institute of Medicine (IOM) and the American Society for Endocrinology advocate different levels of vitamin D to maintain bone health: ≥20 ng/ml and ≥30 ng/ml, respectively. There is no consensus on whether bone cells and immune cells require different levels of vitamin D. In addition to the lack of consensus on the normal range values for vitamin D, the toxic serum concentration and the concentration leading up to this condition are also controversial. In adults, doses greater than or equal to 10,000 IU/day are associated with hypercalcemia.

High performance liquid chromatography (HPLC) followed by mass spectrometry is considered the gold standard for analysis of serum 25-OH vitamin D levels. However, the technique is laborious, expensive, and is not available in most Brazilian laboratories. Other methods such as chemiluminescence, enzyme immunoassay, and radioimmunoassay are also used. Thus, variability in results can occur depending on the assay used. In Brazil, there is no efficient inter-laboratory validation system, which can also result in great variability in results. Moreover, certain medications such as anticonvulsants and corticosteroids may have a role in reducing serum levels of vitamin D.

**SAFETY PROFILE**

The safety profile of different serum vitamin D levels has been evaluated in an open, randomized study conducted in Canada. In that study, a group of 25 patients with MS used escalating cholecalciferol (vitamin D3) doses up to 40,000 IU/day, whereas a second group of 24 patients used 4,000 IU/day. Patients in both groups used immunomodulators (interferon beta and glatiramer acetate) in combination with cholecalciferol. The maximum 40,000 IU/day dose was used for up to six months, followed by 10,000 IU/day for three months and gradual suspension over three months. Both groups received calcium (1,200 mg/day) throughout the trial, and serum calcium was determined. Serum 25-hydroxivitamin D (25-OH-vitamin D) reached a maximum mean above 250 nmol/l (100 ng/ml) during the 40,000 IU/day dosing period. No hypercalcemia was detected during the 10,000 IU/day dosing period, even with serum levels ≥ 100 ng/ml, suggesting that that dose is safe (Class level II evidence). In addition, neither serum calcium nor parathormone urinary levels were altered, even when serum concentrations were higher. Further studies are needed to confirm these findings.

**VITAMIN D – SIDE EFFECTS**

Clinical picture of vitamin D intoxication may include signs and symptoms originating in different systems: nausea and vomiting, anorexia, abdominal pain, constipation; polydipsia, polyuria, dehydration, nephrolithiasis, nephrocalcinosis, nephrogenic diabetes insipidus, chronic interstitial nephritis, acute and chronic renal failure; hypotonia,
paresthesia, confusion, seizures, apathy, coma; arrhythmia, bradycardia, hypertension, cardiomyopathy; muscle weakness, calcification, osteoporosis; and conjunctival calcification. Hypercalcemia is the most important side effect, and when observed in the laboratory is suggestive of intoxication.

During use of vitamin D, in addition to serum calcium, urinary calcium should be assayed periodically. Serum concentration of parathyroid hormone (PTH) should also be determined and must not exceed the lower reference values of normality indicative of suppression, which is a non-recommended condition.

**FINAL CONSIDERATIONS**

Considering the body of information presented here, the DCNI/ABN defines the consensus that:

1. It is recommended to dose vitamin D in patients with clinically isolated syndrome and MS, regardless of the stage of disease, particularly those making frequent use of corticosteroids or anticonvulsivants.
2. Peripheral blood levels of vitamin D lower than 30ng/ml should be corrected in patients with MS, at any stage, or in patients with demyelinating isolated syndrome (grade D recommendation).
3. Peripheral blood levels of vitamin D higher than 100 ng/ml should be avoided until new guidelines are established (grade D recommendation).
4. **There is no scientific evidence up to the production of this consensus for the use of vitamin D as monotherapy for MS in clinical practice.** Therefore, currently, vitamin D monotherapy for MS is considered experimental. For its use in clinical trials, these must be approved by the Human Research Ethics Committee, regulated by the National Commission for Ethics in Research (CONEP), approved by the Regional Medical Board, and informed consent should be provided by patients.
5. According to data from in vitro studies with peripheral blood cells of patients using vitamin D, serum levels above 40 ng/ml are likely to cause modulating action on immune cells. Based on that evidence, vitamin D supplementation at doses that maintain serum levels of patients between 40 ng/ml and 100 ng/ml may be recommended, as these are safe levels (grade D recommendation).
6. Considering the individual differences in replacement needs and serum levels of vitamin D, that a study in healthy subjects showed that 5,000 IU/day of vitamin D for 15 weeks increased serum levels up to 60ng/ml, and that doses up to 10,000 IU/day were considered safe, we recommend individualized doses until reaching serum levels between 40 ng/ml and 100 ng/ml (grade D recommendation).
7. Considering that low vitamin D serum levels in patients with isolated demyelinating syndrome could affect the relative risk of conversion to MS, we recommend the analysis of serum vitamin D levels in those patients and that a correction is made whenever necessary (grade D recommendation).
8. Because vitamin D3 is a secosteroid hormone, its use should be escalated. Moreover, monitoring serum 25-hydroxivitamin D would be extremely important before increasing dosage to determine whether supplementation is actually effective (grade D recommendation).
